

Symmetries of plane partitions and the permanent-determinant method

Greg Kuperberg

Abstract

In the paper [13], Stanley gives formulas for the number of plane partitions in each of ten symmetry classes. This paper together with the two papers [1] and [14] completes the project of proving all ten formulas.

We enumerate cyclically symmetric, self-complementary plane partitions. We first convert plane partitions to tilings of a hexagon in the plane by rhombuses, or equivalently to matchings in a certain planar graph. We can then use the permanent-determinant method or a variant, the Hafnian-Pfaffian method, to obtain the answer as the determinant or Pfaffian of a matrix in each of the ten cases. We row-reduce the resulting matrix in the case under consideration to prove the formula. A similar row-reduction process can be carried out in many of the other cases, and we analyze three other symmetry classes of plane partitions for comparison.

1 Introduction

In the paper [13], Richard Stanley describes ten symmetry classes of plane partitions and gives formulas for their enumeration. We give a brief summary of the conjectures and results mentioned in the paper:

A plane partition is a finite union π of unit cubes in the positive octant of $\mathbb{R}^3$ such that for each cube C in π , there is either another cube or a wall of the octant below C , and the same is true behind and to the left of C . (Sometimes this arrangement is called the Ferrer's diagram of a plane partition.) Alternatively, a plane partition is a finite subset of $\mathbb{Z}_+ \times \mathbb{Z}_+ \times \mathbb{Z}_+$ which is an order ideal with respect to the partial ordering $(x+1, y, z), (x, y+1, z), (x, y, z+1) \geq (x, y, z)$ for $(x, y, z) \in \mathbb{Z}_+^3$. An example of an ordinary but useful plane partition is a box $B(a, b, c) = [0, a] \times [0, b] \times [0, c]$. We define three actions on the set of pairs $(\pi, B(a, b, c))$, where $\pi \subseteq B(a, b, c)$:

1. We define $\tau(\pi)$, the transpose of π , to be $\{(x, y, z) | (y, x, z) \in \pi\}$, and $\tau(\pi, B(a, b, c))$ to be $(\tau(\pi), B(b, a, c))$.
2. We define $\rho(\pi)$, the rotation of π , to be $\{(x, y, z) | (y, z, x) \in \pi\}$, and $\rho(\pi, B(a, b, c))$ to be $(\rho(\pi), B(c, a, b))$.
3. We define $\kappa(\pi, B(a, b, c)) = (\pi', B(a, b, c))$, where π' is the complement of π in $B(a, b, c)$ with all three coordinates reversed. Whenever a box $B(a, b, c)$ has been chosen, we may write $\kappa(\pi)$ for π' by abuse of notation.

Let T be the group generated by τ , ρ , and κ . For each subgroup G of T , we define $N_G(a, b, c)$ to be the number of pairs $(\pi, B(a, b, c))$ fixed by G (in general, $N_G(a, b, c)$ is zero unless $B(a, b, c)$ is fixed by G). There are ten inequivalent choices $G_1, \dots, G_{10}$ for G ; we set $N_i(a, b, c) = N_{G_i}(a, b, c)$. Table 1 gives the definition of each of the ten groups, together with the corresponding formula for N_i . In the table, $H(n)$ is the hyperfactorial function and $H_k(n)$ is a staggered hyperfactorial, defined by $H_k(n) = (n-k)!(n-2k)!(n-3k)! \dots$, $H(n) = H_1(n)$, and $F_k(n) = n(n-k)(n-2k) \dots$ is a staggered factorial. The symbol $\stackrel{!}{=}$ indicates that the equality was conjectural before this paper.

In this paper, we will obtain an expression for each of the ten numbers $N_1, \dots, N_{10}$ as the determinant or the Pfaffian of a matrix. We will then row- and column-reduce the matrices to prove the formulas in Table 1 in cases 1, 3, (part of) 5, and 9. The author has also found a way to evaluate the determinants of the matrices for cases 2, 6, 7, and 8, but remains confounded by cases 4 and 10. The author feels that

Group	Formula		
$G_1 = \langle e \rangle$	$N_1(a, b, c)$	=	$\frac{H(a+b+c)H(a)H(b)H(c)}{H(a+b)H(a+c)H(b+c)}$
$G_2 = \langle \tau \rangle$	$N_2(a, a, b)$	=	$\frac{H_2(2a+b+1)H(a)H_2(b)}{H_2(2a+1)H(a+b)}$
$G_3 = \langle \rho \rangle$	$N_3(a, a, a)$	=	$\frac{H_3(3a+2)H(a)}{H(2a)F_3(3a-2)}$
$G_4 = \langle \tau, \rho \rangle$	$N_4(a, a, a)$	=	$\frac{H_2(a)H_6(3a+5)}{H_2(2a+1)F_6(3a-2)}$
$G_5 = \langle \kappa \rangle$	$N_5(2a, 2b, 2c)$	=	$N_1(a, b, c)^2$
	$N_5(2a, 2b, 2c+1)$	=	$N_1(a, b, c)N_1(a, b, c+1)$
	$N_5(2a+1, 2b+1, 2c)$	=	$N_1(a+1, b, c)N_1(a, b+1, c)$
$G_6 = \langle \kappa\tau \rangle$	$N_6(a, a, 2b)$	=	$\frac{H_2(2b+1)H_2(2b+2a)H(a)}{H(2b+a)H_2(2a)}$
$G_7 = \langle \kappa, \tau \rangle$	$N_7(2a, 2a, 2b)$	=	$N_1(a, a, b)$
	$N_7(2a+1, 2a+1, 2b)$	=	$N_1(a, a+1, b)$
$G_8 = \langle \kappa\tau, \rho \rangle$	$N_8(2a, 2a, 2a)$	=	$\frac{F_3(3a-2)H_6(6a)H_2(2a)}{H_4(4a+1)H_4(4a)}$
$G_9 = \langle \kappa, \rho \rangle$	$N_9(2a, 2a, 2a)$	$\stackrel{!}{=}$	$\frac{H_3(3a+1)^2 H(a)^2}{H(2a)^2}$
$G_{10} = \langle \kappa, \tau, \rho \rangle$	$N_{10}(2a, 2a, 2a)$	=	$\frac{H_3(3a+1)H(a)}{H(2a)}$

Table 1: Enumeration formulas for symmetric plane partitions

the permanent-determinant method is a good first step towards a unified treatment of all ten cases, but the entirety of such a treatment remains elusive.

The proofs of cases 4 and 10 are more recent than the results of this paper and will appear in [14] and [1]. These three results conclude the problem of enumeration of plane partitions in different symmetry classes, although the problem of q -enumeration (see section 5) remains open in case 4. Table 2 gives an account of who first conjectured and who first proved the formula in each symmetry class. In particular, the formula in case 9, whose proof is the main news of this paper, in Table 3 gives the same information for q -enumeration. The tables are largely compiled from [13]. They list the number of the symmetry class as given by Stanley, the name in the convention of Stembridge, and the generators in the notation of this paper.

Our plan is to combine two old ideas about combinatorial tilings. The first idea has probably been known since antiquity, and is illustrated in [3] and [12] and discussed in great generality in [16]. It is that a plane partition in a box is equivalent to a tiling by certain rhombuses of a certain hexagon. To convert a plane partition to a tiling, we view the partition as a union of unit cubes in an $a \times b \times c$ box, and we simply “draw

a picture” of the partition, together with the back three sides of the box:

We decree that the hexagon has angles of $2\pi/3$ and congruent opposite sides of lengths a , b , and c (we will call such a hexagon semi-regular), and the rhombuses have angles of $\pi/3$ and $2\pi/3$ and unit edge length (we will call such a rhombus a lozenge). Conversely, we can “look at” a tiling and “see” the corresponding partition. We invite the reader to arrive at this visual proof by staring at some representative rhombus tilings.

The three operations τ , ρ , and κ have a simple interpretation in terms of tilings. The operation τ is a reflection about a diagonal between two opposite vertices, ρ is a rotation by $2\pi/3$ (clockwise by convention), and κ is a rotation by π . For example, the number $N_9(2a, 2a, 2a)$ is also the number of lozenge tilings of a regular hexagon which are invariant under rotation by $\pi/3$.

Suppose we are given a tiling of a semi-regular hexagon H by lozenges. There is a unique tiling of H by unit equilateral triangles. We may form a graph Z whose vertices are these triangles, with two vertices connected when the triangles are adjacent. Each tiling by rhombuses corresponds to a (perfect) matching in Z . This brings us to the second idea, the permanent-determinant method, which can be used to count the number of matchings in a bipartite planar graph, and the Hafnian-Pfaffian method, a generalization for non-bipartite graphs. The general method is due to Kasteleyn [10] [9], but was motivated by an important special case independently discovered by Kasteleyn [8] and Temperley and Fisher [15], which in turn expanded on ideas of Hurst and Green [6], Caianiello [2], and Kac and Ward [7]. The permanent-determinant case of the method was noted by Percus [11].

We can use the permanent-determinant method in cases 1, 3, 6, and 8. The Hafnian-Pfaffian method applies in the remaining cases.

This paper is a result of a collaboration with James Propp, who has maintained a steady interest in its contents and its completion, and the ideas presented here grew out of those in [4, 5]. In particular I would like to thank him for correcting many minor errors in the final version. I would also like to thank William Jockusch, Richard Stanley, John Stembridge, and my former advisor, Andrew Casson, for encouragement and helpful discussions.

2 Definition of the general methods

We begin with a brief overview of four functions of matrices known as the permanent, determinant, Hafnian, and Pfaffian.

Let A be an $n \times n$ matrix. The permanent of A is a sum over permutations of n letters:

$$\text{Per}(A) = \sum_{\sigma \in S_n} \prod_{i=1}^n A_{i, \sigma(i)}$$

The determinant is a signed sum of the same type:

$$\text{Det}(A) = \sum_{\sigma \in S_n} (-1)^\sigma \prod_{i=1}^n A_{i, \sigma(i)}$$

In general, the permanent of a matrix is hard to compute (see [17]) and satisfies relatively few interesting identities, while the determinant is a fundamental object of all mathematics and can be computed in polynomial time.

A (perfect) matching of a set S of $2n$ objects is a set of n disjoint pairs of elements of S . A matching is ordered or unordered depending on whether its members are ordered or unordered pairs. Let U_n be the set of unordered matchings among $2n$ objects, and let O_n be the set of ordered matchings. The Hafnian and the Pfaffian are polynomials which bear the same relationship to unordered matchings that the permanent and determinant do to ordered matchings, although the Pfaffian is most conveniently defined by ordered matchings. (Both the term ‘‘Hafnian’’ and the polynomial it denotes were devised by Caianiello, who explains that the Hafnian, like the element Hafnium, is named after the city of Copenhagen.) Like a permutation, an ordered matching has a sign: The matching $(1, 2), (3, 4), \dots, (2n-1, 2n)$ is defined to be positive, and if σ is a permutation of $2n$ elements and m is an ordered matching, then the sign of $\sigma(m)$ is defined to be the product of the signs of m and σ .

If A is a symmetric $2n \times 2n$ matrix, the Hafnian of A is defined to be the sum:

$$\text{Hf}(A) = \sum_{m \in U_n} \prod_{\{i, j\} \in m} A_{i, j}$$

If A is an antisymmetric $2n \times 2n$ matrix, the Pfaffian of A is defined to be the sum:

$$\text{Pf}(A) = \frac{1}{2^n} \sum_{m \in O_n} (-1)^m \prod_{(i, j) \in m} A_{i, j}$$

After close scrutiny of this formula, it becomes clear that the use of oriented matchings is a notational device and the Pfaffian is really a polynomial with one term (with a leading coefficient of ± 1) for each unoriented matching. The Hafnian is a generalization of the permanent and the Pfaffian is a generalization of the determinant, because if

$$A = \left(\begin{array}{c|c} 0 & B \\ \hline B & 0 \end{array} \right)$$

and

$$A' = \left(\begin{array}{c|c} 0 & B \\ \hline -B & 0 \end{array} \right),$$

then

$$\text{Hf}(A) = \text{Per}(B)$$

and

$$\text{Pf}(A') = \text{Det}(B)$$

Being a generalization of the permanent, the Hafnian is also in general intractible. But the Pfaffian satisfies the important identities

$$\text{Pf}(B^T A B) = \text{Det}(B) \text{Pf}(A)$$

and

$$\text{Pf}(A)^2 = \text{Det}(A),$$

which are closely related to each other. For a proof of these assertions about the Pfaffian, see [10]. It is also an instructive exercise to develop both the above definition of the Pfaffian and its properties from the following alternative definition: If the anti-symmetric matrix A is viewed as the matrix of a 2-form $\omega_A \in \bigwedge^2 \mathbb{R}^{2n}$, and μ is the standard volume form on $\mathbb{R}^{2n}$, then:

$$\omega_A^{\wedge n} = \text{Pf}(A)\mu.$$

Let Z be a bipartite graph with black vertices $b_1, \dots, b_n$ and white vertices $w_1, \dots, w_n$. We define the bipartite adjacency matrix M_Z of Z by setting $(M_Z)_{i,j}$ to be the number of edges from b_i to w_j . We see that the permanent of M_Z is simply the number of matchings in Z . More generally, if Z_w is a weighted version of Z , we define $(M_{Z_w})_{i,j}$ to be the total weight of all edges from b_i to w_j . The permanent of M_{Z_w} is the total weight of all matchings in Z_w , where the weight of a matching in Z_w is the product of the weights of the edges of the matching.

Suppose that Z is planar and is given with a specific planar embedding, and suppose Z_w is a weighted version of Z . We wish to obtain a new weighting $Z_{w'}$, by changing the sign of some of the weights, so that:

$$\text{Det}(M_{Z_{w'}}) = \pm \text{Per}(M_{Z_w}) \quad (1)$$

on a term-by-term basis. We define the weights of Z_w to be the product of those of Z and the weights of a signed graph $Z_{\pm}$. We say that $Z_{\pm}$ is flat if for every face of Z (in the given embedding) that has $4k$ sides, an odd number of sides are negative in $Z_{\pm}$; and for every face that has $4k+2$ sides, an even number of sides are negative in $Z_{\pm}$.

For the Hafnian-Pfaffian case, let Z be a weighted graph which is not necessarily bipartite. If S_Z is the usual symmetric, weighted adjacency matrix of Z , then $\text{Hf}(S_Z)$ is the weighted sum of all matchings in Z .

To have a Pfaffian, we need an anti-symmetric matrix. We let Z_w be an oriented, weighted graph with vertices $v_1, \dots, v_n$. We define the anti-symmetric incidence matrix A_{Z_w} of Z_w by $A_{i,j} = w_{i,j} - w_{j,i}$, where $w_{i,j}$ is the total weight of all edges from v_i to v_j .

Suppose that Z is an unoriented weighted graph with a given planar embedding. We wish to orient the edges of Z to obtain a graph $\vec{Z}_w$ so that:

$$\text{Pf}(A_{\vec{Z}_w}) = \pm \text{Hf}(S_{Z_w}) \quad (2)$$

Once again, we use a consistency rule: We say that the orientation of $\vec{Z}_w$ is flat if each face F of $\vec{Z}_w$ has an odd number of edges which point in the clockwise direction around F .

Kasteleyn's theorem states that every planar graph has a flat orientation, and that equation 2 holds if $\vec{Z}_w$ is flat. These results have an excellent treatment in [10] which would not be improved if it were repeated here. However, just as the determinant is an interesting special case of the Pfaffian, the permanent-determinant method is an interesting special case of the Hafnian-Pfaffian method that admits a self-contained treatment that we present here:

Theorem 2.1. *Every planar, bipartite graph Z with an even number of vertices has at least one flat weighting $Z_{\pm}$.*

Proof. We view Z as embedded in the sphere and we will achieve flatness on the outside face as well as the others. (In fact, it is impossible to have flatness on all but one face on the sphere.) Let f_0 be the number of faces with $4k$ sides, let f_2 be the number of faces with $4k+2$ sides, and let e and v be the number of edges and vertices. Then $e = f_2 \bmod 2$ while $v = 0 \bmod 2$. Therefore the Euler characteristic equation $f_0 + f_2 - e + v = 2$ reduces to $f_2 = 0 \bmod 2$, or in other words, an even number of faces have $4k+2$ sides. Choose a matching among these faces and connect their centers with paths on the sphere which are transverse to Z . If an edge of Z is crossed by n paths, give it a weight of $(-1)^n$ in $Z_{\pm}$. Since every path enters and leaves a face with $4k$ sides the same number of times, $Z_{\pm}$ is flat at such a face. For a face with $4k+2$ sides, the number of entries has the opposite parity from the number of exits, therefore $Z_{\pm}$ is flat here also. $\square$

Theorem 2.2. *If Z_w is an arbitrary weighting of a planar bipartite graph Z , $Z_{\pm}$ is a flat signing, and $Z_{w'}$ is the product weighting, then:*

$$\text{Det}(M_{Z_{w'}}) = \pm \text{Per}(M_{Z_w})$$

Proof. We would like to prove that all terms in $\text{Det}(M_{Z_{w'}})$ have the same relative sign compared to the corresponding terms in $\text{Per}(M_{Z_w})$. It suffices to show that all terms in $\text{Det}(M_{Z_{\pm}})$ have the same sign. For simplicity we assume that Z has at most one edge connecting any pair of vertices.

We first note that if a cycle c in Z , not necessarily the boundary of a face, encircles an even number of vertices, then the cycle has an even number negative edges if it has $4k + 2$ sides and an odd number if it has $4k$ sides. (Proof: We define $Z_{c,\pm}$ by removing all edges and vertices of $Z_{\pm}$ outside of c . We know that $Z_{c,\pm}$ is flat at every internal face and we want to show it is flat on the outside face as well. To do this we show that any signed graph $G_{\pm}$ with an even number of vertices has an even number of non-flat sides. By the proof of lemma 2.1, we know that $G_{\pm}$ has an even number of faces with $4k$ sides. If $G_{\pm}$ has the trivial signing, these are precisely the sides which are not flat. But if the sign of an edge is reversed, the flatness of precisely two sides is reversed.)

Let m_1 and m_2 be two matchings in Z , and let σ_1 and σ_2 be the corresponding permutations. The set $m_1 \cup m_2 - m_1 \cap m_2$ is a union of disjoint cycles, each encircling an even number of vertices of Z , and there is a sequence of matchings in Z connecting m_1 to m_2 such that two consecutive matchings in the sequence differ by only one cycle. We want to show that the terms for all of these matchings have the same sign. Therefore we can assume by induction that $m_1 \cup m_2 - m_1 \cap m_2$ consists of a single cycle c .

Suppose that c has length $2n$. (By construction it alternates between edges of m_1 and m_2 and therefore has even length.) Then the permutation $\sigma_2^{-1}\sigma_1$ is an n -cycle, which is an even permutation if n is odd and vice-versa. Therefore the relative signs of the permutations is exactly canceled by the relative signs of the edges of m_1 and m_2 , which is given by the number of negative edges in c . $\square$

The rows and columns of the matrices in this paper will in general be indexed by an unordered index set rather than by the integers from 1 to n for some n . The Pfaffian of such a matrix is only defined up to sign, and since the rows and the columns may have different index sets, the determinant has the same ambiguity. Therefore we will work instead with the absolute determinant or absolute Pfaffian (the absolute value of the determinant of Pfaffian), which are still unambiguous quantities in this case.

3 Enumeration in the simplest case

In this section we give a complete proof of the formula for the number of plane partitions in case 1. The analysis of case 1 will set a pattern for the other cases and will also be used as a lemma.

We will explicitly define matrices whose determinants or Pfaffians are the answers to the ten counting problems.

Let $H(a, b, c)$ denote a semi-regular hexagon with edge lengths a , b , and c . Let $T(a, b, c)$ be the tiling of $H(a, b, c)$ by equilateral triangles of unit edge length. We can divide the triangles of $T(a, b, c)$ into two kinds, ∇ triangles and Δ triangles:

We define a graph $Z(a, b, c)$ with vertex set $T(a, b, c)$, where two triangles are connected by an edge if and only if they are adjacent. $Z(a, b, c)$ might look like this:

We give $Z(a, b, c)$ the “default” weighting, whereby the weight of each edge is 1. Evidently, $Z(a, b, c)$ is bipartite, and we can take the labels ∇ and Δ as a standard bicoloring.

We see that a matching in $Z(a, b, c)$ corresponds to a plane partition in $B(a, b, c)$. Thus, $N_1(a, b, c)$ is simply the number of matchings in $Z(a, b, c)$. Let $M(a, b, c)$ be the bipartite adjacency matrix of $Z(a, b, c)$. We decree that the ∇ triangles are the rows of $M(a, b, c)$ and the Δ triangles are the columns. To apply the permanent-determinant method, we need to find a new matrix whose determinant equals $\text{Per}(M(a, b, c))$. In this case, all of the faces of $Z(a, b, c)$ except the outside face have six sides. Therefore not changing the weights of $Z(a, b, c)$ at all is a flat sign rule. In other words,

$$|\text{Det}(M(a, b, c))| = \text{Per}(M(a, b, c)) = N_1(a, b, c). \quad (3)$$

We have obtained a determinant which we must evaluate. We proceed by row- and column-reduction and by induction on the area of $H(a, b, c)$.

We embed $H(a, b, c)$ in $H(a + 1, b + 1, c - 1)$ as follows:

We embed $T(a, b, c)$ in $T(a + 1, b + 1, c - 1)$ and $M(a, b, c)$ in $M(a + 1, b + 1, c - 1)$ in the corresponding way.

We label the triangles in and adjacent to $T(a+1, b+1, c-1) - T(a, b, c)$ with the labels x_i , y_i , z_i , and l :

We can use each label twice, once for a ∇ triangle and once for a Δ triangle. We use these labels to write out some pieces of the matrix $M(a+1, b+1, c-1)$. For example, let D be the submatrix whose rows are l and the x_i 's and whose columns are the y_i 's and z_i 's. Note that D^T also appears as a submatrix in the symmetrical position. In the case $c = 4$, the matrix D looks like this:

	y_1	y_2	y_3	z_0	z_1	z_2	z_3
l	1	0	0	1	0	0	0
x_1	1	1	0	0	1	0	0
x_2	0	1	1	0	0	1	0
x_3	0	0	1	0	0	0	1

If we multiply D by the matrix E :

	l	x_1	x_2	x_3
l	1	-1	1	-1
x_1	0	1	-1	1
x_2	0	0	1	-1
x_3	0	0	0	1

on the left, we obtain the product:

	y_1	y_2	y_3	z_0	z_1	z_2	z_3
l	0	0	0	1	-1	1	-1
x_1	1	0	0	0	1	-1	1
x_2	0	1	0	0	0	1	-1
x_3	0	0	1	0	0	0	1

Since E has determinant 1, and since the x_i and l rows and columns are zero outside of D and D^T , we can replace D and D^T by ED and $D^T E^T$ in $M(a+1, b+1, c-1)$ to obtain a new matrix $M'(a, b, c)$ with the same determinant.

The x_i and y_i rows and columns are irrelevant to the absolute determinant of the matrix $M'(a, b, c)$, because the x_i row (column) is the only row (column) in which the y_i column (row) is non-zero, and the entries at the intersections of these rows and columns are all ± 1 . If we delete these rows and columns we obtain a matrix $R(a, b, c)$ which still has the same absolute determinant. This matrix is simply $M(a, b, c)$ with an extra row and column labelled l . To complete the description of $R(a, b, c)$, we note that $R(a, b, c)_{l, z_i} = R(a, b, c)_{z_i, l} = (-1)^i$ and $R(a, b, c)_{l, t} = 0$ or $R(a, b, c)_{t, l} = 0$ where t is any triangle which is not a z_i triangle.

We are left with the problem of reducing the l row. Since $M(a, b, c)$ is invertible (because, by induction its determinant is the number of plane partitions and there is at least one of them), we know that there is some linear combination of the $M(a, b, c)$ rows which matches the l row exactly except for the $R(a, b, c)_{l, l}$ entry. We choose a coefficient α_t for each ∇ triangle $t \in T(a, b, c)$ so that:

$$\sum_t \alpha_t R(a, b, c)_{t, u} + R(a, b, c)_{l, u} = 0$$

for each Δ triangle $u \in T(a, b, c)$. After adding α_t times the t row to the l row for each t , we obtain a new matrix $R'(a, b, c)$ for which:

$$R'(a, b, c)_{l,l} = \sum_t \alpha_t R(a, b, c)_{t,l}$$

The matrix $R'(a, b, c)$ still has the same absolute determinant as $M(a+1, b+1, c-1)$ and has the form:

$$\left(\begin{array}{cccc|c} & & & & \cdot \\ & & & & \cdot \\ & & & & \cdot \\ & & & & \cdot \\ & & & & \cdot \\ \hline 0 & 0 & 0 & \dots & 0 & r \end{array} \right)$$

where $r = R'(a, b, c)_{l,l}$. Therefore:

$$|\text{Det}(M(a+1, b+1, c-1))| = |R'(a, b, c)_{l,l}| |\text{Det}(M(a, b, c))|, \quad (4)$$

which will prove the inductive step. For convenience, we define $\alpha_i = \alpha_{z_i}$ and $\beta_i = R(a, b, c)_{l,z_i} = R(a, b, c)_{z_i,l}$, where i is an integer. Observe that $\beta_i = (-1)^i$.

Let s, t, u , and v be four adjacent triangles in the middle of $H(a, b, c)$ arranged as follows:

We see that the corresponding α coefficients satisfy a symmetric Pascal triangle rule:

$$\alpha_s + \alpha_t + \alpha_u = -R(a, b, c)_{l,v} = 0$$

The β_i coefficients may be incorporated into this rule, because if s, t , and z_i are arranged as follows:

then:

$$\alpha_s + \alpha_t + R(a, b, c)_{l,z_i} = \alpha_s + \alpha_t + \beta_i = 0$$

If we put each coefficient α_t inside the triangle t , and each β_i under the Δ triangle z_i , we see that each number is the negative of the sum of the two above it:

(In this figure the coefficients have all been multiplied by 4 to clear denominators.) Thus, we get a set of linear equations for the α_i 's in terms of β_i 's:

$$\beta_{c-1-i} = (-1)^{a+b} \sum_j \binom{a+b}{b+i-j} \alpha_j \quad (5)$$

Strictly speaking, the summation over j should be from 0 to $c-1$ and the equation is only valid for i from 0 to $c-1$. However, if we declare that $\alpha_i = 0$ and β_i is an indeterminate for $i < 0$ and $i \geq c$, then the equation will be valid for all i and the summation can be extended to go from $-\infty$ to ∞ . (Recall that out-of-bounds binomial coefficients are zero by common convention if the top index is a non-negative integer and the bottom index is an integer. Among other things this implies that the β_i 's must have finite support if the α_i 's do.) All subsequent summations will run over all of $\mathbb{Z}$ unless otherwise noted.

We also get an expression for the final answer in terms of the α_i and β_i coefficients:

$$R'(a, b, c)_{l,l} = \sum_i \alpha_i \beta_i.$$

The author originally obtained the solution to these equations with the aid of MACSYMATM, but with hindsight we may use generating functions to make the computation look easy. We will work in the formal power series ring $\mathbb{R}[[x, y]][1/x, 1/y]$ (which should not be confused with $\mathbb{R}((x, y))$). Keeping in mind that the α_i and β_i are implicitly functions of a, b , and c , we define these generating functions:

$$\begin{aligned} A(a, b, c; x) &= \sum_i \alpha_i x^i \\ A(a, b; x, y) &= \sum_{c=0}^{\infty} A(a, b, c; x) y^{c-1} \\ M(a, b; x) &= (-1)^{a+b} x^{-b} (1+x)^{a+b} \\ M(a, b; x, y) &= M(a, b; x) = (-1)^{a+b} x^{-b} y^{-a-b} (xy+y)^{a+b} \\ B(a, b, c; x) &= \sum_i \beta_{c-1-i} x^i \\ B(a, b; x, y) &= \sum_{c=0}^{\infty} B(a, b, c; x) y^{c-1} \end{aligned}$$

Then the equation

$$B(a, b, c; x) = M(a, b; x) A(a, b, c; x),$$

which is equivalent to

$$B(a, b; x, y) = M(a, b; x, y) A(a, b; x, y),$$

is also equivalent to equation 5. By the definition of the β_i coefficients,

$$B(a, b; x, y) = \frac{1}{(1-xy)(1+y)} + \dots$$

where the ellipses here and below represent indeterminate or irrelevant terms with either more factors of x than y or negative powers of x , and $A(a, b; x, y)$ is to be determined. Proceeding directly to the answer, we set:

$$A(a, b; x, y) = \frac{(-1)^{a+b}}{(1-xy)^{a+1} (1+y)^{b+1} \binom{a+b}{a}}$$

We apply the binomial expansion theorem:

$$\begin{aligned} M(a, b; x, y) A(a, b; x, y) &= \frac{((1+y) - (1-xy))^{a+b}}{x^b y^{a+b} (1-xy)^{a+1} (1+y)^{b+1} \binom{a+b}{a}} \\ &= \sum_{k=0}^{a+b} \frac{\binom{a+b}{k} (-1)^k (1-xy)^k (1+y)^{a+b-k}}{x^b y^{a+b} (1-xy)^{a+1} (1+y)^{b+1} \binom{a+b}{a}} \end{aligned}$$

A given term in this sum with $k < a$, when expanded in x and y , has more factors of x than y , while a term with $k > a$ has only negative powers of x . Therefore, only the $k = a$ term contributes to the coefficients of $B(a, b; x, y)$ that we have constrained. We compute:

$$\begin{aligned} M(a, b; x, y)A(a, b; x, y) &= \dots + \frac{(-1)^a}{x^b y^{a+b} (1-xy)(1+y)} + \dots \\ &= \dots + \frac{1}{(1-xy)(1+y)} + \dots \\ &= B(a, b; x, y), \end{aligned}$$

as desired. In the second line of the equation we again discard terms with more factors of x than y or negative powers of x .

Finally, we recall:

$$R'(a, b, c)_{l,l} = \sum_i \alpha_i \beta_i = A(a, b, c; -1)$$

and we compute:

$$\sum_{c=0}^{\infty} A(a, b, c; -1) y^{c-1} = A(a, b; -1, y) = \frac{(-1)^{a+b}}{\binom{a+b}{a} (1+y)^{a+b+2}}$$

Using the power series expansion:

$$\frac{1}{(1-x)^k} = \sum_n \binom{n+k-1}{n} x^n,$$

we obtain:

$$R'(a, b, c)_{l,l} = (-1)^{a+b+c-1} \binom{a+b+c}{c-1} \bigg/ \binom{a+b}{a}, \quad (6)$$

or equivalently, by equations 3 and 4:

$$\frac{N_1(a+1, b+1, c-1)}{N_1(a, b, c)} = \binom{a+b+c}{c-1} \bigg/ \binom{a+b}{a},$$

which is the desired ratio.

For comparison with the other cases of enumeration, we introduce an extra subscript for many of the quantities defined here. We will use $\alpha_{1,i}$ for α_i , $\beta_{1,i}$ for β_i , A_1 for A , and B_1 for B .

4 Determinants and Pfaffians for matchings with symmetries

In this section, we will analyze the set of matchings of a graph which are invariant under some group action. We will then apply this analysis to the particular group actions on the graph $Z(a, b, c)$ under consideration. The result for each group will be a planar graph whose matchings correspond to plane partitions with the equivalent symmetry. We can then use the permanent-determinant or Hafnian-Pfaffian method to reduce each of the ten enumerations to questions about matrices.

Suppose that Z is a finite graph with a distinguished vertex called “bachelorhood”. We define a matching with bachelors in Z to be a matching in which every vertex is matched to exactly one of its neighbors, except for the bachelorhood vertex, which can be matched to any subset of its neighbors. (Note that there may be more than one edge between the bachelorhood vertex and another vertex. We define the bachelor’s degree of a vertex to be the number of edges connecting it to the bachelorhood vertex.) The concept of matchings with bachelors is a generalization of ordinary matchings in the sense that if Z is an ordinary graph, we let Z' be Z together with an isolated bachelorhood vertex, and a matching in Z will correspond to a matching with bachelors in Z' .

Given a graph Z with a bachelorhood vertex, we wish to construct a graph Z' such that ordinary matchings in Z' correspond to matchings with bachelors in Z . For this purpose we can replace the bachelorhood

vertex of Z by a subgraph which consists of either a row of triangles:

or a row of triangles and an edge:

The first subgraph has the property that if an odd number of vertices are matched to the outside, the remainder can be matched among themselves in a unique way, and the second subgraph has the analogous property for an even number of vertices. (The proof of this fact is left as an exercise to the reader.) Thus, we replace the bachelorhood vertex by one of these two graphs in such a way that the total number of vertices is even and call the result Z' . The graph Z' has exactly one matching for each matching with bachelors of Z . Moreover, if Z is a planar graph, it is possible to construct Z' to be planar also.

Suppose that Z is a graph with a bachelorhood vertex (which may be isolated) and a group G acts on Z . That is, each element of G is some permutation of the vertices that fixes the bachelorhood vertex and edges of Z that preserves the relation of an edge containing a vertex. We wish to construct a modified quotient graph $Z//G$ whose matchings are bijective with G -invariant matchings of Z . If e is an edge reversed by G , i.e. there exists an element of G which fixes e but switches its endpoints, we replace e by an edge from each of its endpoints to the bachelorhood vertex. We perform this operation for all edges reversed by G and call the result Z' . The action of G on Z extends to an action on Z' , and the G -invariant matchings of Z' can be identified with the G -invariant matchings of Z . Suppose that e is an edge of Z' with a vertex v which is not the bachelorhood vertex such that the stabilizer of e does not contain the stabilizer of v . Then e cannot be a member of any G -invariant matching of Z' . Let Z'' be Z' with all such edges removed. Let Z''/G be the usual quotient of a graph by a group action: The vertices of Z''/G are the G -orbits of vertices in Z'' , and two vertices are connected by an edge if the corresponding orbits of vertices are connected by an orbit of edges. Finally, we define $Z//G$ to be Z''/G . The graph $Z//G$ has the property that:

Lemma 4.1. *The matchings of $Z//G$ are in natural bijection with the G -invariant matchings of Z .*

The proof of this lemma is sketched by the definition above.

It is not true in general that if Z is planar then $Z//G$ is also. Indeed, if Z is the edge graph of a hexagonal prism:

then Z has a fixed-point free involution such that the quotient is $K_{3,3}$, namely the involution consisting of rotation by 180 degrees and transposition of the inner and outer hexagons. However, suppose that

$Z = Z(a, b, c)$ for some a , b , and c , with an isolated bachelorhood vertex added, and suppose that $G = G_i$ for some $2 \leq i \leq 10$. Then $Z(a, b, c)/G_i$ is indeed a planar graph in these cases. We further modify Z/G to remove the bachelorhood vertex and call the result $Z_i(a, b, c)$. If i is 3 or 9, or if i is 5 and a , b , and c all have the same parity, then G_i acts freely on $Z(a, b, c)$ and the quotient graph is particularly simple. When $\kappa\tau \in G_i$, namely in cases 6, 7, 8, and 10, the vertices and edges of $Z(a, b, c)$ fixed by $\kappa\tau$ or its conjugates map to a collection of disjoint edges in $Z_i(a, b, c)$, which can be ignored since there is only one matching in a graph which is itself a matching. When $\tau \in G_i$, namely in cases 2, 4, 7, and 10, $Z_i(a, b, c)$ has a non-trivial bachelorhood vertex, so it is necessary to modify it in the manner described above to obtain a planar graph without a bachelorhood vertex. Finally, in cases 3, 6, and 8, the end result is a bipartite graph, and therefore the permanent-determinant method is applicable. In the other six cases, the Hafnian-Pfaffian method must be used.

5 Determinants and Pfaffians for q -enumeration

The previous two sections describe how to construct matrices whose determinants and Pfaffians enumerate plane partitions in each of the ten symmetry classes. The permanent-determinant method applied to weighted graphs yields matrices whose determinants and Pfaffians q -enumerate plane partitions in various ways. In particular, the natural q -enumerations described in [13] for cases 1, 2, 3, and 4 can all be expressed this way. In this section we give a determinant for q -enumeration in the simplest case, case 1, as an illustration of the general principle.

We define the q -weight of a plane partition to be q^n if the plane partition has n elements. We wish to find the total q -weight of all plane partitions in an $a \times b \times c$ box. We say that two plane partitions in such a box differ by an elementary move if they are the same except for one cube. Observe that we can connect any two plane partitions in a box by a sequence of elementary moves. If two plane partitions differ by an elementary move, the corresponding matchings in $Z(a, b, c)$ differ on only one hexagon:

In fact, there are two kinds of elementary moves: A raising elementary move is in which a cube is added, while a lowering elementary move is one in which a cube is deleted.

We wish to weight the edges of $Z(a, b, c)$ in such a way that the weight of a matching agrees with the weight of the corresponding plane partition. If we find such a weighting with the property that if we perform a raising elementary move on a matching, the weight goes up by a factor of q , then the total weight of all matchings will equal the total weight of all plane partitions up to a constant factor. That constant factor is the weight of the matching corresponding to the empty plane partition, because the q -weight of the empty plane partition is 1. To accomplish this we give all slanted edges in $Z(a, b, c)$ and all of the left-most vertical edges a weight of 1. The weight of any other vertical edge is q times the weight of the edge immediately to

the left of it. The result is of the following form:

The bipartite adjacency matrix of this graph has the desired determinant up to a normalization factor.

The total q -weight is also an interesting statistic in cases 2, 3, and 4, and in each of these cases the same method yields a matrix whose determinant or Pfaffian is the desired statistic. However, there is no known formula for the total q -weight of all plane partitions in case 4 in this sense. For the purpose of understanding case 4, there is an alternative weighting scheme: The q -weight of a plane partition is defined to be q^n if the plane partition contains n orbits under the required symmetry group. The total orbit- q -weight satisfies a nice formula in cases 2 and 4, and again in those two cases as well as in case 3 the above method yields a determinant or Pfaffian. The orbit- q -enumeration of plane partitions in case 4 remains the only open enumeration in the standard conjectures about symmetric plane partitions.

6 Enumeration in a previously open case

The ultimate goal of this section is to prove the formulas for $N_3(a, a, a)$, $N_5(2a, 2b, 2c)$, and $N_9(2a, 2a, 2a)$ by counting matchings in $Z_3(a, a, a)$, $Z_5(2a, 2b, 2c)$, and $Z_9(2a, 2a, 2a)$. The hard part of the proof will be row- and column-reduction. The proof in case 1 will be used as a template and as a lemma. In addition, the three cases treated here together with case 1 form an analogy:

case 1	is to	case 3
is to	as	is to
case 5	is to	case 9

Recall that the vertices of $Z(a, b, c)$ are the triangles in a tiling $T(a, b, c)$ of a hexagon $H(a, b, c)$:

Since $Z_3(a, a, a)$ is a quotient graph of $Z(a, a, a)$, its vertices are ρ -orbits $\{t, \rho(t), \rho^2(t)\}$ of elements of $T(a, a, a)$. (One of the ρ -orbits in the picture is shaded.) Moreover, two vertices of $Z_3(a, a, a)$ are connected

by an edge if and only if they are adjacent as ρ -orbits. (Note that there is a pair of ρ -orbits in the middle which are connected by two edges.) Observe that elements of a ρ -orbit are either all ∇ triangles or Δ triangles, so we can speak of ∇ ρ -orbits and Δ ρ -orbits. In other words, the bicoloring of $Z(a, a, a)$ carries over to a bicoloring of $Z_3(a, a, a)$. As in case 1, the trivial sign rule is flat, so if we let $M_3(a, a, a)$ be the bipartite adjacency matrix of $Z_3(a, a, a)$, its determinant is $N_3(a, a, a)$. We decree that the ∇ ρ -orbits should index the rows of $M_3(a, a, a)$ and the Δ ρ -orbits should index the columns.

The vertices of $Z_5(2a, 2b, 2c)$ are pairs of triangles $\{t, \kappa(t)\}$, where one triangle is a ∇ triangle and the other is a Δ triangle. Since the graph $Z_5(2a, 2b, 2c)$ is not bipartite, we will need to examine its antisymmetric adjacency matrix under some flat orientation rule, and such a matrix $M_5(2a, 2b, 2c)$ would have one row and one column for every vertex of $Z_5(2a, 2b, 2c)$. Instead of having the rows and columns indexed by these vertices, we can as in case 1 have the rows of $M_5(2a, 2b, 2c)$ indexed by ∇ triangles and the columns by Δ triangles, because each ∇ triangle corresponds to a unique pair and vice-versa, and the same is true of the Δ triangles. With this indexing, we can take advantage of the fact that $M_5(2a, 2b, 2c)$ (with any orientation for $Z_5(2a, 2b, 2c)$) is simultaneously the bipartite adjacency matrix for some (non-flat) signed version of $Z(2a, 2b, 2c)$. The signs must be chosen so that the an edge from t to u is the negative of the edge from κt to κu , and it must also correspond to a flat orientation. One such weighting is characterized by the following map:

In this weighting, the edge between two adjacent triangles which are below the center of $H(2a, 2b, 2c)$ has weight -1 , as does the edge between two triangles which are to the right of the center if one is below the center and one is above the center. All other edges have weight 1 . We let $M_5(2a, 2b, 2c)$ be the bipartite adjacency matrix of this weighted graph. It is antisymmetric and its Pfaffian is $N_5(2a, 2b, 2c)$.

The same analysis holds for $Z_9(2a, 2a, 2a)$, except that the antisymmetric adjacency matrix of an oriented version of this graph is simultaneously the bipartite adjacency matrix of a weighted version of $Z_3(2a, 2a, 2a)$. We give $Z_3(2a, 2a, 2a)$ the following weighting:

and we let $M_9(2a, 2a, 2a)$ be the bipartite adjacency matrix of the result. One way to describe this weighting

is to say that if t and u are adjacent triangles, then:

$$M_9(2a, 2a, 2a)_{\{t, \rho(t), \rho^2(t)\}, \{u, \rho(u), \rho^2(u)\}} = M_5(2a, 2a, 2a)_{t, u} M_5(2a, 2a, 2a)_{\rho(t), \rho(u)} M_5(2a, 2a, 2a)_{\rho^2(t), \rho^2(u)}$$

The only exception to this rule is in the very center: If t and u are the two ρ -orbits of triangles in the very center of $H(2a, 2a, 2a)$, then $M_9(2a, 2a, 2a)_{t, u} = 0$.

We embed $M_3(a, a, a)$ in $M_3(a+1, a+1, a+1)$, $M_5(2a, 2b, 2c)$ in $M_5(2a+2, 2b+2, 2c-2)$, and $M_9(2a, 2a, 2a)$ in $M_9(2a+2, 2a+2, 2a+2)$. The corresponding embeddings of semi-regular hexagons look like this:

In each case, we label many rows and columns of the larger matrix for the purpose of row-reduction by

labeling the corresponding triangles or ρ -orbits:

Case 3

Case 5

Case 9

With these labels, the row-reduction algorithm has the same basic plan as in case 1: For $i = 3, 5$, or 9 , we define a matrix $R_i(a, b, c)$ by multiplying the x_i rows and columns, the l row and column, and (if it exists), the k row and column by a certain matrix with determinant 1. In the result the x_j and y_j rows and columns will be irrelevant, and the only non-zero entries of the l and k rows will be in the z_j , l , and k columns. However, the actual values of those entries will be somewhat different. In all three cases, we define $\beta_{i,j} = R_i(a, b, c)_{l,z_j}$ and in cases 5 and 9 we also define $\gamma_{i,j} = R_i(a, b, c)_{z_j,k}$.

In the final row-reduction step we will find a linear combination of the rows of $M_i(a, b, c)$ which matches the l row exactly except for the $R(a, b, c)_{l,l}$ coefficient and, if it is defined, the $R(a, b, c)_{l,k}$ coefficient. We choose a coefficient $\alpha_{i,t}$ for each row t of $M_i(a, b, c)$ so that:

$$\sum_t \alpha_{i,t} R(a, b, c)_{t,u} + R(a, b, c)_{l,u} = 0$$

for each column u . In case 3, we add $\alpha_{3,t}$ times the t row to the l for each t to obtain a matrix $R'_3(a, b, c)$. Just as in case 1, the result is:

$$|\text{Det}(M_3(a+1, a+1, a+1))| = |R'_3(a, a, a)_{l,l}| |\text{Det}(M_3(2a, 2a, 2a))|$$

In cases 5 and 9, we add $\alpha_{i,t}$ times the t row to the l row and then add $\alpha_{i,t}$ times the $\kappa(t)$ column to the l column to obtain $R'_5(2a, 2b, 2c)$ or $R'_9(2a, 2a, 2a)$. All operations performed to obtain these two matrices will

be symmetric with respect to rows and columns, and as a result these two matrices must be antisymmetric as $M_5(2a, 2b, 2c)$ and $M_9(2a, 2a, 2a)$ are. The matrix $R'_5(2a, 2b, 2c)$ will have this form:

$$\left(\begin{array}{cccc|cc} & & & & 0 & \cdot \\ & & & & 0 & \cdot \\ & & & & 0 & \cdot \\ & & & & \vdots & \vdots \\ & & & & 0 & \cdot \\ \hline 0 & 0 & 0 & \dots & 0 & \\ \cdot & \cdot & \cdot & \dots & \cdot & -r & 0 \end{array} \right)$$

where $r = R'_5(2a, 2b, 2c)_{l,k}$. From the form of the matrix we obtain a relation for the absolute Pfaffian:

$$|\text{Pf}(M_5(2a+2, 2b+2, 2c-2))| = |R'_5(2a, 2b, 2c)_{l,k}| |\text{Pf}(M_5(2a, 2b, 2c))|$$

and by the same argument for case 9,

$$|\text{Pf}(M_9(2a+2, 2a+2, 2a+2))| = |R'_9(2a, 2a, 2a)_{l,k}| |\text{Pf}(M_9(2a, 2a, 2a))|$$

To derive the actual entries of the matrices $R_i(a, b, c)$ and $R'_i(a, b, c)$ and the coefficients $\alpha_{i,j} = \alpha_{i,z_j}$, we proceed on a case-by-case basis. As before, once the $\alpha_{i,j}$'s are chosen, the values of the other $\alpha_{i,t}$'s can be determined in a simple manner.

6.1 Case 3

In case 3, the submatrix indexed by x_i and l rows and y_i and z_i columns looks the same as in case 1, but we must include the l and x_a columns because $M_3(a+1, a+1, a+1)_{l,x_a}$ and $M_3(a+1, a+1, a+1)_{x_a,l}$ are non-zero. Here is the submatrix D which covers all non-zero entries of the l and x_i rows in the case $a = 3$:

	x_3	y_1	y_2	y_3	z_0	z_1	z_2	l
l	1	1	0	0	1	0	0	0
x_1	0	1	1	0	0	1	0	0
x_2	0	0	1	1	0	0	1	0
x_3	0	0	0	1	0	0	0	1

If we multiply D by the matrix E :

	l	x_1	x_2	x_3
l	1	-1	1	-1
x_1	0	1	-1	1
x_2	0	0	1	-1
x_3	0	0	0	1

on the left, we obtain the product:

	y_1	y_2	y_3	z_0	z_1	z_2	l
l	0	0	0	1	-1	1	-1
x_1	1	0	0	0	1	-1	1
x_2	0	1	0	0	0	1	-1
x_3	0	0	1	0	0	0	1

Since E has determinant 1, and since the x_i and l rows are zero outside of D , we can replace D by ED in $M_3(a+1, a+1, a+1)$ without altering the determinant. However, notice that in case 3 there is an intersection of a single entry, $M_3(a, a, a)_{l,l}$, between D and D_T , and multiplying D on the left by E alters this entry. Nevertheless we still multiply on the right by E^T . We again delete the x_i and y_i rows and columns to obtain $R_3(a, a, a)$. This matrix consists of $M_3(a, a, a)$ plus the non-zero entries $\beta_{3,i} = R_3(a, a, a)_{l,z_i} = R_3(a, a, a)_{z_i,l} = (-1)^i$ and also $R_3(a, a, a)_{l,l} = (-1)^a 2$. We are left with the derivation of the $\alpha_{3,i}$'s.

We can interpret the $\alpha_{3,t}$ coefficients as a function on individual triangles in $T(a, a, a)$ rather than ρ -orbits by the equation:

$$\alpha_{3,t} = \alpha_{3,\{t, \rho(t), \rho^2(t)\}}$$

Like the $\alpha_{1,t}$'s, the $\alpha_{3,t}$'s satisfy the symmetric Pascal rule in $H(a, a, a)$, but the boundary conditions are different. To extend the symmetric Pascal rule to the boundary, we must place the $\beta_{3,i}$ coefficients on all of the triangles in the ρ -orbits of x_i , not just on the bottom row:

We obtain the solution by setting:

$$\alpha_{3,t} = \alpha_{1,t} + \alpha_{1,\rho(t)} + \alpha_{1,\rho^2(t)}$$

for all triangles $t \in T(a, a, a)$. For integers i , we also define $\alpha'_{1,i} = \alpha_{1,\rho(z_i)}$ and $\alpha''_{1,i} = \alpha_{1,\rho^2(z_i)}$.

We expand $R'_3(a, a, a)_{l,l}$:

$$\begin{aligned} R'_3(a, a, a)_{l,l} &= R_3(a, a, a)_{l,l} + \sum_i (-1)^i \alpha_{1,i} + \sum_i (-1)^i \alpha'_{1,i} + \sum_i (-1)^i \alpha''_{1,i} \\ &= (-1)^a 2 + (-1)^{3a-1} \binom{3a}{a-1} \Big/ \binom{2a}{a} + 2 \sum_i (-1)^i \alpha'_{1,i} \end{aligned} \quad (7)$$

by equation 6 and by the symmetry $\alpha_{1,\tau\kappa(t)} = (-1)^{a+1} \alpha_{1,t}$, which implies that $\alpha''_{1,i} = (-1)^{a+1} \alpha'_{1,a-1-i}$. From the position of $\rho(z_i)$ in $H(a, a, a)$ (recall that ρ is a clockwise rotation), we obtain the formula:

$$\alpha'_{1,i} = (-1)^{a+i} \sum_j \binom{a+i}{2a-1-j} \alpha_{1,j}$$

Therefore:

$$\sum_i (-1)^i \alpha'_{1,i} = (-1)^a \sum_{i,j} \binom{a+i}{2a-1-j} \alpha_{1,j} = (-1)^a \sum_j \binom{2a}{2a-j} \alpha_{1,j} = (-1)^a \beta_{1,-1}$$

Recall that $\beta_{1,-1}$ is the x^a coefficient of the polynomial $B_1(a, a, a; x)$ and the $x^a y^{a-1}$ coefficient of $B_1(a, a; x, y)$. We compute:

$$\begin{aligned} B_1(a, a, a; x, y) &= M_1(a, a; x, y) A_1(a, a, a; x, y) = \frac{((1+y) - (1-xy))^{2a}}{x^a y^{2a} (1-xy)^{a+1} (1+y)^{a+1} \binom{2a}{a}} \\ &= \sum_k \frac{\binom{2a}{k} (-1)^k (1-x)^k (1+y)^{2a-k}}{x^a y^{2a} (1-xy)^{a+1} (1+y)^{a+1} \binom{2a}{a}} \end{aligned}$$

Both the $k = 0$ term and the $k = a$ term, but no other terms, contribute to the $x^a y^{a-1}$ coefficient:

$$\begin{aligned} B_1(a, a, a; x, y) &= \frac{(1+y)^{a-1}}{x^a y^{2a} (1-xy)^{a+1} \binom{2a}{a}} + \frac{(-1)^a}{x^a y^{2a} (1-xy)(1+y)} + \dots \\ &= x^a y^{a-1} \left(\binom{3a}{a} / \binom{2a}{a} - 1 \right) + \dots \end{aligned} \quad (8)$$

Substituting equation 8 in equation 7, we have:

$$R'_3(a, a, a)_{l,l} = (-1)^a \left(2 - \binom{3a}{a-1} / \binom{2a}{a} + 2 \binom{3a}{a} / \binom{2a}{a} - 2 \right) = (-1)^a \frac{3a+2}{a} \binom{3a}{a-1} / \binom{2a}{a}$$

This is the desired ratio up to sign.

6.2 Case 5

In the two Pfaffian cases, the x_i triangles near a given edge of the hexagon form two rows rather than one and as a result the initial row-reduction step is more complicated. As before, we consider the submatrix D of $M_5(2a+2, 2b+2, 2c-2)$ consisting of the x_i , l , and k rows and the y_i and z_i columns. Here is D when $c = 2$:

	y_1	y_2	y_3	y_4	y_5	y_6	y_7	y_8	y_9	z_0	z_1	z_2	z_3	z_4	z_5
k	-1	0	0	0	-1	0	0	0	0	0	0	0	0	0	0
x_1	-1	-1	0	0	0	-1	0	0	0	0	0	0	0	0	0
x_2	0	-1	-1	0	0	0	-1	0	0	0	0	0	0	0	0
x_3	0	0	-1	-1	0	0	0	-1	0	0	0	0	0	0	0
x_4	0	0	0	-1	0	0	0	0	-1	0	0	0	0	0	0
l	0	0	0	0	-1	0	0	0	0	-1	0	0	0	0	0
x_5	0	0	0	0	-1	-1	0	0	0	0	-1	0	0	0	0
x_6	0	0	0	0	0	-1	-1	0	0	0	0	-1	0	0	0
x_7	0	0	0	0	0	0	-1	-1	0	0	0	0	-1	0	0
x_8	0	0	0	0	0	0	0	-1	-1	0	0	0	0	-1	0
x_9	0	0	0	0	0	0	0	0	-1	0	0	0	0	0	-1

Note that $-D^T$ also appears as a submatrix of $M_5(2a+2, 2b+2, 2c-2)$. If we multiply D by a matrix E of the form:

	k	x_1	x_2	x_3	x_4	l	x_5	x_6	x_7	x_8	x_9
k	1	-1	1	-1	1	0	-1	2	-3	4	-5
x_1	0	1	-1	1	-1	0	0	-1	2	-3	4
x_2	0	0	1	-1	1	0	0	0	-1	2	-3
x_3	0	0	0	1	-1	0	0	0	0	-1	2
x_4	0	0	0	0	1	0	0	0	0	0	-1
l	0	0	0	0	0	1	-1	1	-1	1	-1
x_5	0	0	0	0	0	0	1	-1	1	-1	1
x_6	0	0	0	0	0	0	0	1	-1	1	-1
x_7	0	0	0	0	0	0	0	0	1	-1	1
x_8	0	0	0	0	0	0	0	0	0	1	-1
x_9	0	0	0	0	0	0	0	0	0	0	1

We obtain:

	y_1	y_2	y_3	y_4	y_5	y_6	y_7	y_8	y_9	z_0	z_1	z_2	z_3	z_4	z_5
k	0	0	0	0	0	0	0	0	0	0	1	-2	3	-4	5
x_1	-1	0	0	0	0	0	0	0	0	0	0	1	-2	3	-4
x_2	0	-1	0	0	0	0	0	0	0	0	0	0	1	-2	3
x_3	0	0	-1	0	0	0	0	0	0	0	0	0	0	1	-2
x_4	0	0	0	-1	0	0	0	0	0	0	0	0	0	0	1
l	0	0	0	0	0	0	0	0	0	-1	1	-1	1	-1	1
x_5	0	0	0	0	-1	0	0	0	0	0	-1	1	-1	1	-1
x_6	0	0	0	0	0	-1	0	0	0	0	0	-1	1	-1	1
x_7	0	0	0	0	0	0	-1	0	0	0	0	0	-1	1	-1
x_8	0	0	0	0	0	0	0	-1	0	0	0	0	0	-1	1
x_9	0	0	0	0	0	0	0	0	-1	0	0	0	0	0	-1

We replace D by ED and $-D^T$ by $-D^T E^T$ in $M_5(2a+2, 2b+2, 2c-2)$, and then delete the x_i and y_i rows and columns to obtain $R_5(2a, 2b, 2c)$, which still has the same absolute Pfaffian. In addition to $M_5(2a, 2b, 2c)$, the matrix $R_5(2a, 2b, 2c)$ has the non-zero entries $\beta_{5,i} = R_5(2a, 2b, 2c)_{l,z_i} = -R_5(2a, 2b, 2c)_{z_i,l} = -(-1)^i$ and $\gamma_{5,i} = -R_5(2a, 2b, 2c)_{k,z_i} = i(-1)^i$.

The $\alpha_{5,t}$ coefficients, as a function on the ∇ triangles of $T(2a, 2b, 2c)$, satisfy the symmetric Pascal rule everywhere except along a “branch cut” going from the center of $T(2a, 2b, 2c)$ to the right edge, where they satisfy the ordinary Pascal rule:

We label the row of triangles just below the branch cut as indicated and we define $\overline{\alpha}_{5,i} = \alpha_{5,u_i}$.

We define the following generating functions:

$$\begin{aligned}
A_5(2a, 2b, 2c; x) &= \sum_i x^i \alpha_{5,i} \\
\overline{A}_5(2a, 2b, 2c; x) &= \sum_i x^i \overline{\alpha}_{5,i} \\
B_5(2a, 2b, 2c; x) &= \sum_i x^i \beta_{5,2c-i}
\end{aligned}$$

For convenience in dealing with the branch cut, we define the function $\theta(n)$ to be -1 when $n \geq 0$ and 1 when $n < 0$. We define the functions σ and $\tilde{\sigma}$ on Laurent polynomials by:

$$\begin{aligned}
\sigma(P(x)) &= \sum_i \theta(i) p_i x^i \\
\tilde{\sigma}(P(x)) &= \sum_{i \neq 0} \theta(i) p_i x^i
\end{aligned}$$

where:

$$P(x) = \sum_i x^i p_i.$$

We examine the equations that the $\bar{\alpha}_{5,i}$ coefficients satisfy:

$$\bar{\alpha}_{5,i} = (-1)^{a+b} \theta(i) \sum_j \binom{a+b}{a+c+i-j} \alpha_{5,j} \quad (9)$$

$$\beta_{5,2c-i} = (-1)^{a+b} \sum_j \binom{a+b}{a-c+i-j} \bar{\alpha}_{5,j} \quad (10)$$

We can put equations 9 and 10 in generating function form:

$$\begin{aligned} \bar{A}_5(2a, 2b, 2c; x) &= \sigma(x^{-c} M_1(a, b; x) A_5(2a, 2b, 2c; x)) \\ B_5(2a, 2b, 2c; x) &= x^c M_1(a, b; x) \bar{A}_5(2a, 2b, 2c; x) \end{aligned}$$

As before, for $i > 2c - 1$ or $i < 0$, $\alpha_{5,i} = 0$, but $\beta_{5,i}$ is indeterminate.

As usual, we jump to the solution (originally found with the aid of MATHEMATICA™) by setting

$$A_5(2a, 2b, 2c; x) = (1+x) A_1(a, b, c; x)^2.$$

Before demonstrating that this is the solution, we define the polynomials $B_L(a, b, c; x)$ and $B_H(a, b, c; x)$ by:

$$B_1(a, b, c; x) = M_1(a, b; x) A_1(a, b, c; x) = (-1)^{c-1} \frac{1}{1+x} + B_L(a, b, c; x) + B_H(a, b, c; x), \quad (11)$$

where $B_H(a, b, c; x)$ has no terms with exponents less than c , and $B_L(a, b, c; x)$ consists only of terms with negative exponents. By analogy with $B_1(a, b, c; x)$, we also define:

$$\begin{aligned} B_H(a, b, c; x) &= \sum_i \beta_{H, c-1-i} x^i \\ B_L(a, b, c; x) &= \sum_i \beta_{L, c-1-i} x^i \end{aligned}$$

Using the fact that the terms of $A_1(a, b, c; x)$ have degrees from 0 to $c - 1$ inclusive, we can expand $\bar{A}_5(2a, 2b, 2c; x)$:

$$\begin{aligned} \bar{A}_5(2a, 2b, 2c; x) &= \sigma(x^{-c} M_1(a, b; x) (1+x) A_1(a, b, c; x)^2) \\ &= \sigma(x^{-c} (1+x) A_1(a, b, c; x) \left(\frac{(-1)^{c-1}}{(1+x)} + B_L(a, b, c; x) + B_H(a, b, c; x) \right)) \\ &= x^{-c} (1+x) A_1(a, b, c; x) \left(\frac{(-1)^{c-1}}{(1+x)} + B_L(a, b, c; x) - B_H(a, b, c; x) \right) \end{aligned}$$

The result is a cancellation of the “error terms” B_H and B_L :

$$\begin{aligned} x^c M_1(a, b; x) \bar{A}_5(2a, 2b, 2c; x) &= (1+x) \left(\frac{(-1)^{c-1}}{1+x} + B_L(a, b, c; x) + B_H(a, b, c; x) \right) \left(\frac{(-1)^{c-1}}{1+x} + B_L(a, b, c; x) - B_H(a, b, c; x) \right) \\ &= \frac{1}{1+x} + (-1)^{c-1} 2B_L(a, b, c; x) + (1+x)(B_L(a, b, c; x)^2 - B_H(a, b, c; x)^2) \\ &= B_5(2a, 2b, 2c; x) \end{aligned} \quad (12)$$

Finally, since $\gamma_{5,i} = i(-1)^i$, we see that:

$$R'_5(2a, 2b, 2c)_{l,k} = \left. \frac{dA_5(2a, 2b, 2c; x)}{dx} \right|_{x=-1} = A(a, b, c; -1)^2 = R'(a, b, c)_{l,l}^2 \quad (13)$$

6.3 Case 9

Case 9 is similar to case 3 in the sense that the positions in which the k , l , and x_i rows are non-zero in the matrix $M_9(2a+2, 2a+2, 2a+2)$ include the l and k columns as well as the y_i and z_i columns. We let D be the submatrix consisting of all of these rows and columns. Here is D when $a = 4$:

	y_1	y_2	y_3	y_4	y_5	y_6	y_7	y_8	y_9	z_0	z_1	z_2	z_3	l	k
k	-1	0	0	0	-1	0	0	0	0	0	0	0	0	0	0
x_1	-1	-1	0	0	0	-1	0	0	0	0	0	0	0	0	0
x_2	0	-1	-1	0	0	0	-1	0	0	0	0	0	0	0	0
x_3	0	0	-1	-1	0	0	0	-1	0	0	0	0	0	0	0
x_4	0	0	0	1	0	0	0	0	1	0	0	0	0	0	0
l	0	0	0	0	-1	0	0	0	0	-1	0	0	0	0	0
x_5	0	0	0	0	-1	-1	0	0	0	0	-1	0	0	0	0
x_6	0	0	0	0	0	-1	-1	0	0	0	0	-1	0	0	0
x_7	0	0	0	0	0	0	-1	-1	0	0	0	0	-1	0	0
x_8	0	0	0	0	0	0	0	1	1	0	0	0	0	1	0
x_9	0	0	0	0	0	0	0	0	1	0	0	0	0	0	1

Some of the entries are positive, because unlike case 5, in case 9 the ∇ triangles x_a , x_{2a} , and x_{2a+1} lie outside of the negative region in the sign rule map for the matrix $M_9(2a+2, 2a+2, 2a+2)$.

Note that $-D^T$ also appears as a submatrix of $M_9(2a+2, 2a+2, 2a+2)$ but that the two matrices intersect in the 2×2 matrix formed by l and k . We multiply D by a matrix E of the form:

	k	x_1	x_2	x_3	x_4	l	x_5	x_6	x_7	x_8	x_9
k	1	-1	1	-1	-1	0	-1	2	-3	-4	5
x_1	0	1	-1	1	1	0	0	-1	2	3	-4
x_2	0	0	1	-1	-1	0	0	0	-1	-2	3
x_3	0	0	0	1	1	0	0	0	0	1	-2
x_4	0	0	0	0	-1	0	0	0	0	0	1
l	0	0	0	0	0	1	-1	1	-1	-1	1
x_5	0	0	0	0	0	0	1	-1	1	1	-1
x_6	0	0	0	0	0	0	0	1	-1	-1	1
x_7	0	0	0	0	0	0	0	0	1	1	-1
x_8	0	0	0	0	0	0	0	0	0	-1	1
x_9	0	0	0	0	0	0	0	0	0	0	-1

This matrix is the same as the one in case 5, except that the x_a , x_{2a} , and x_{2a+1} columns have been negated. The product in this case is:

	y_1	y_2	y_3	y_4	y_5	y_6	y_7	y_8	y_9	z_0	z_1	z_2	z_3	l	k
k	0	0	0	0	0	0	0	0	0	0	1	-2	3	-4	5
x_1	-1	0	0	0	0	0	0	0	0	0	0	1	-2	3	-4
x_2	0	-1	0	0	0	0	0	0	0	0	0	0	1	-2	3
x_3	0	0	-1	0	0	0	0	0	0	0	0	0	0	1	-2
x_4	0	0	0	1	0	0	0	0	0	0	0	0	0	0	1
l	0	0	0	0	0	0	0	0	0	-1	1	-1	1	-1	1
x_5	0	0	0	0	-1	0	0	0	0	0	-1	1	-1	1	-1
x_6	0	0	0	0	0	-1	0	0	0	0	0	-1	1	-1	1
x_7	0	0	0	0	0	0	-1	0	0	0	0	0	-1	1	-1
x_8	0	0	0	0	0	0	0	-1	0	0	0	0	0	-1	1
x_9	0	0	0	0	0	0	0	0	-1	0	0	0	0	0	-1

In the matrix $M_9(2a+2, 2a+2, 2a+2)$, we multiply D by E on the left, which affects the l - k submatrix of $-D^T$, and then we multiply the modified version of $-D^T$ by E^T on the right. After multiplying on the left, the l - k submatrix is in general:

$$\begin{array}{c|cc} & k & l \\ \hline k & 2a+1 & -2a \\ l & 1 & -1 \end{array}$$

and after multiplying on the right, it becomes:

$$\begin{array}{c|cc} & k & l \\ \hline k & 0 & -2a-1 \\ l & 2a+1 & 0 \end{array}$$

We delete the x_i and y_i rows and columns and call the result $R_9(2a, 2a, 2a)$. In addition to the above submatrix and the submatrix $M_9(2a, 2a, 2a)$, $R_9(2a, 2a, 2a)$ also has the non-zero entries $\beta_{9,i} = R_9(2a, 2b, 2c)_{l,z_i} = -R_9(2a, 2b, 2c)_{z_i,l} = -(-1)^i$ and $\gamma_{9,i} = -R_9(2a, 2b, 2c)_{k,z_i} = i(-1)^i$.

As in case 3, we interpret the $\alpha_{9,t}$ coefficients as a function on triangles in $T(2a, 2a, 2a)$ by the following equation:

$$\alpha_{9,t} = \alpha_{9,\{t,\rho(t),\rho^2(t)\}}$$

The resulting coefficients satisfy the symmetric Pascal rule everywhere except along three branch cuts instead of one:

We can recycle the computations of case 5 by setting $\tilde{\alpha}_{5,t} = \alpha_{5,t}$ for all $t \in T(2a, 2a, 2a)$ except those which lie in the region R between the two branch cuts on the left side. For $t \in R$, we set $\tilde{\alpha}_{5,t} = -\alpha_{5,t}$. We see that the $\alpha_{9,t}$'s satisfy the same rule as the $\tilde{\alpha}_{5,t}$'s, except with different boundary conditions. Following case 3, we can obtain the former from the latter by symmetrization:

$$\alpha_{9,t} = \tilde{\alpha}_{5,t} + \tilde{\alpha}_{5,\rho(t)} + \tilde{\alpha}_{5,\rho^2(t)}$$

We define:

$$\alpha'_{5,i} = \tilde{\alpha}_{5,\rho(z_i)} = \alpha_{5,\rho(z_i)}$$

$$\alpha''_{5,i} = \tilde{\alpha}_{5,\rho^2(z_i)} = -\alpha_{5,\rho^2(z_i)}$$

(Recall that ρ is a clockwise rotation.) We expand $R'_9(2a, 2a, 2a)_{l,k}$:

$$\begin{aligned} R'_9(2a, 2a, 2a)_{l,k} &= R_9(2a, 2a, 2a)_{l,k} + \sum_i i(-1)^i \alpha_{5,i} + \sum_i i(-1)^i \alpha'_{5,i} + \sum_i i(-1)^i \alpha''_{5,i} \\ &= 2a+1 + \binom{3a}{a-1}^2 / \binom{2a}{a}^2 + \sum_i (-1)^i (2i-2a-1) \alpha'_{5,i} \end{aligned} \quad (14)$$

from equation 13 and from the symmetry $\alpha_{5,t} = -\alpha_{5,\kappa_T(t)}$, which holds for triangles t below the center of $T(2a, 2a, 2a)$ and which implies that $\alpha''_{5,i} = -\alpha'_{5,2a-1-i}$. From the position of $\rho(z_i)$ in $T(2a, 2a, 2a)$, we learn that:

$$\alpha'_{5,i} = (-1)^i \sum_j \binom{2a+i}{4a-1-j} \alpha_{5,j}$$

Therefore:

$$\begin{aligned}
\sum_i (-1)^i (2i - 2a - 1) \alpha'_{5,i} &= \sum_{i,j} (2i - 2a - 1) \binom{2a+i}{4a+1-j} \alpha_{5,j} \\
&= \sum_j \left((2a-1) \binom{4a}{4a-j} - 2 \binom{4a}{4a+1-j} \right) \alpha_{5,j} \\
&= 2\beta_{5,-2} - (2a-1)\beta_{5,-1}
\end{aligned} \tag{15}$$

We want to know $\beta_{5,-1}$ and $\beta_{5,-2}$, which are the x^{2a} and x^{2a+1} coefficients of $B_5(2a, 2a, 2a; x)$. If we combine equations 11 and 12, we obtain:

$$\begin{aligned}
B_5(2a, 2a, 2a; x) &= \frac{1}{1+x} - (1+x)B_H(a, a, a; x)^2 + \dots \\
&= \dots + x^{2a} - x^{2a+1} + \dots - (1+x)(\beta_{H,-1}x^a + \beta_{H,-2}x^{a+1} + \dots)^2 \\
&= (1 - \beta_{H,-1}^2)x^{2a} + (-1 - \beta_{H,-1}(2\beta_{H,-2} + \beta_{H,-1}))x^{2a+1} + \dots
\end{aligned} \tag{16}$$

Putting together equations 14, 15, and 16, we obtain:

$$R'_9(2a, 2a, 2a)_{l,k} = \frac{a^2}{(3a+1)^2} \binom{3a+1}{a}^2 \bigg/ \binom{2a}{a}^2 - \beta_{H,-1}(4\beta_{H,-2} - (2a-3)\beta_{H,-1})$$

We know from equation 8 that:

$$\beta_{H,-1} = \binom{3a}{a} \bigg/ \binom{2a}{a} = \frac{2a+1}{3a+1} \binom{3a+1}{a} \bigg/ \binom{2a}{a}$$

We can obtain $\beta_{H,-2}$ in the same way we derived $\beta_{H,-1}$:

$$\begin{aligned}
B_1(a, a, a; x, y) &= \frac{(1+y)^{a-1}}{x^a y^{2a} (1-xy)^{a+1} \binom{2a}{a}} - \frac{2a(1+y)^a - 2}{x^a y^{2a} (1-xy)^a \binom{2a}{a}} + \dots + \frac{(-1)^a}{x^a y^{2a} (1+y)(1-xy)} + \dots \\
&= (a-1)x^{a+1}y^{a-1} \binom{3a+1}{a} \bigg/ \binom{2a}{a} - 2ax^{a+1}y^{a-1} \binom{3a}{a-1} \bigg/ \binom{2a}{a} + \dots \\
&+ x^{a+1}y^{a-1} + \dots
\end{aligned}$$

Thus:

$$\beta_{H,-2} = \frac{a^2 - 2a - 1}{3a+1} \binom{3a+1}{a} \bigg/ \binom{2a}{a}$$

and:

$$R'_9(a, a, a)_{l,k} = \frac{9a^2 + 6a + 1}{(3a+1)^2} \binom{3a+1}{a}^2 \bigg/ \binom{2a}{a}^2 = \binom{3a+1}{a}^2 \bigg/ \binom{2a}{a}^2$$

This is the desired answer.
